Mediterranean semi-enclosed bays are often exposed to high levels of contaminants originating from anthropogenic activities in the bay. To assess their fate and impact on the environment, it is essential to investigate coastal circulation regimes which may play an important role in the dispersion of contaminants across the bay and beyond. In this study, a high resolution coupled hydrodynamic - passive tracer model was combined with ADCP observations, to identify major circulation patterns and associated dissolved contaminant dispersion pathways in the contaminated semi-enclosed bay of Toulon (South of France, NW Mediterranean Sea). Two dominant circulation patterns and two derived ones could be identified, driven by winds (Mistral

60
61
62
63
64 and easterly winds) and offshore waters intrusions. Medium to strong Mistral
65 events (superior to 6 m s^{-1}) with a WNW direction cause a bi-layer pattern
66
67 with surface waters flowing out of the bay and marine waters entering at
68
69 depth. Less frequently, Western Mistral winds of medium to strong strength
70
71 (superior to 6 m s^{-1}) may generate an anticyclonic circulation. During east-
72
73 erly wind conditions ($> 6 \text{ m s}^{-1}$), an inward flow can be observed which
74
75 is sometimes reinforced by offshore waters intrusions, probably from the lo-
76
77 cal boundary current, the Northern Current (NC). Furthermore, dissolved
78
79 contaminant dispersion pathways were simulated under typical wind forcing
80
81 conditions with three source points of copper (Cu) that were identified based
82
83 on surface Cu observations. While most of the WNW Mistral wind events
84
85 transport dissolved copper plumes across and out of the bay, contaminant
86
87 dispersion can remain confined to the bay under certain west mistral con-
88
89 ditions. Conversely, during easterly wind events, contaminants are exiting
90
91 the bay as a narrow vein along the Saint-Mandrier peninsula, before prob-
92
93 ably converging on the NC offshore. Accordingly, this study demonstrates
94
95 the important impact of hydrodynamic-driven processes on the dispersion of
96
97 contaminants within a semi-enclosed bay.

1. Introduction

Today, marine coastal areas suffer from an extremely high anthropogenic pressure, which is the result of a continuous development of human activities in these areas for centuries. These activities have lead to pollution hot

113
114
115
116
117
118
119
120 spots, endangering the water quality of ports, beaches, aquaculture zones
121 and marine protected areas, challenging local governments to find a balance
122 between economical and environmental interests. To this end, Toulon Bay
123 (South of France, NW Mediterranean Sea) is an area of interest as it is a
124 semi-enclosed bay harbouring the largest French naval base while located at
125 less than 20 km from the Marine National Park of Port-Cros (Fig. 1). The
126 core of this marine protected area includes two islands within the Hyeres Bay,
127 namely Porquerolles and Port-Cros Islands. The surrounding waters, host-
128 ing a unique marine ecosystem, are highly monitored to maintain its quality,
129 protect its biodiversity and promote a sustainable development of tourism
130 and local communities. Its proximity to the highly industrialised Toulon city
131 requires a better understanding of contaminant distribution within the bay
132 and its surroundings, to assess its potential impact on the water quality of the
133 national park. The long history of naval, industrial and commercial activities
134 in the Toulon Bay has important environmental consequences for the bay.
135 High concentrations of trace metals (e.g. lead, copper, zinc, ...) have been
136 measured in sediments (Tessier et al., 2011; Pougnet et al., 2014) and surface
137 waters (Dang et al., 2015; Jean et al., 2012; Coclet et al., 2018). For both
138 matrices, the contamination is the strongest in the enclosed north-western
139 part of the bay (i.e. the small Bay (SB)) where surface sediments contain up
140 to ca. 1000 times more mercury compared to background values, while up to
141 80, 40 and 31 times more copper, zinc and lead, respectively (Tessier et al.,
142 2011). Surface waters on the other hand, are ca. 40 and 70-fold enriched
143 in respectively dissolved lead and copper (Coclet et al., 2018), compared to
144 trace metal concentrations observed in the open Mediterranean Sea (Tovar-

169
170
171
172
173
174
175
176 [Sanchez et al., 2014](#)). While Toulon Bay might be considered as one of the
177 most polluted marine areas of the northern Mediterranean sea ([Tessier et al.,](#)
178 [2011](#)), contamination might be exported to offshore waters through hydro-
179 dynamic processes and reach sensitive areas as the Marine National Park of
180 Port-Cros.
181

182
183
184 Very few studies have focused on the hydrodynamic processes within the
185 Toulon Bay. [Millot et al. \(1981\)](#) and [Tine \(1981\)](#) were the first to use current
186 profiler data to quantify water exchanges through the channel between the
187 small (SB) and the large bay (LB), while [Duffa et al. \(2011\)](#), [Dufresne et al.](#)
188 [\(2014\)](#) and [Dufresne et al. \(2018\)](#) recently constructed a hydro-sedimentary
189 model of the Toulon Bay, to create a post-accidental management tool in the
190 event of radionuclide releases to the environment. These studies showed that
191 the circulation is strongly dependent on wind conditions, causing for instance
192 reversals in the water column in the channel connecting the SB with the LB
193 ([Dufresne et al., 2014](#)). While these studies focused on the quantification of
194 the exchanges between the SB and the LB, here we investigate the circulation
195 in the LB under various wind conditions and the resulting exchanges with
196 offshore waters.
197
198

199
200
201 The aim of this study is two-fold. The first objective is to identify dom-
202 inant circulation patterns inside the bay, using an ocean circulation model
203 (MITgcm) and ADCP observations in the Toulon Bay. The second objective
204 is to investigate contaminant transport, by defining dispersion patterns and
205 assess the potential impact on key areas within the bay and beyond.
206
207

208
209
210 After a description of the studied site, the model configuration and in
211 situ observations, we describe the wind-driven circulation within the bay.
212

225
226
227
228
229
230
231 An analysis of the contaminant distribution as observed in March 2017 is
232 discussed and the model is used as a tool to simulate the dispersion of dis-
233 solved contaminants based on wind conditions.
234
235

236 237 238 **2. Material and methods**

239 240 *2.1. Study area*

241
242 The water circulation of the southeast French Mediterranean coast, is
243 characterized by a strong geostrophic boundary current flowing along the
244 North Western Mediterranean Sea coast counter-clockwise, the Northern
245 Current (NC). This current has been largely studied especially focusing on its
246 behaviour upstream in the Ligurian basin ([Taupier-Letage and Millot, 1986](#);
247 [Alberola et al., 1995a](#); [Sammari et al., 1995](#); [Bethoux et al., 1982](#)), down-
248 stream at the eastern side of the Gulf of Lion ([Alberola and Millot, 2003](#);
249 [Conan and Millot, 1995](#); [Flexas et al., 2002](#)), and along its shelf ([Auclair](#)
250 [et al., 2001](#); [Petrenko, 2003](#); [Rubio et al., 2009](#); [Lapouyade and Durrieu de](#)
251 [madron, 2001](#)). However few studies on the NC circulation were conducted in
252 the Var region, which can be seen as an area of transition ([Ourmières et al.,](#)
253 [2011](#); [Guihou et al., 2013](#); [Declerck et al., 2016](#)). These studies showed that
254 in this area the NC has a meso and sub-mesoscale activity which can create
255 exchanges between the shelves and offshore waters. For instance [Declerck](#)
256 [et al. \(2016\)](#) modelled intrusions into the Hyeres Bay, nearby the Toulon
257 Bay. They showed that the NC, through meanders and vortices dynamics,
258 can either act as a barrier or favour in- and off-shore water mixing into semi-
259 enclosed bays as Hyeres Bay. Here, we will focus on the Toulon bay, analyze
260 its inner wind-driven circulation and the possible offshore waters intrusions
261

285
286
287 that may be driven by the Northern Current that flows off the bay.
288

289 Toulon Bay is a shallow semi-closed area (about 10 km x 15 km), divided
290 into two bays, separated by a seawall of 1.4 km long modeled impervious on
291 the whole water column: a small bay (SB; $\approx 10 \text{ km}^2$) which hosts mostly all
292 the anthropogenic activities and a large bay (LB; $\approx 42 \text{ km}^2$) connected to
293 the offshore sea (Fig. 1). The LB is delimited by Cape Carqueiranne to the
294 east, and by the Saint-Mandrier peninsula to the west. At the south of the
295 LB, the bathymetry is very steep with a canyon of ca. 600 m deep.
296
297
298
299
300

301 Since there is no significant tide motion (tidal amplitude of approximately
302 20 cm) (Millot et al., 1981; Alberola et al., 1995b) in the Toulon bay, its
303 circulation is supposed to be mostly wind-driven with possible boundary
304 current intrusions. The wind forcing has an important spatial and temporal
305 variability with strong events (Millot et al., 1981; Dufresne et al., 2014).
306 Three wind situations can be distinguished: Mistral, easterly wind and calm
307 weather. Toulon is surrounded by mountains that deflect these winds: the
308 Mistral blows from the west/north-west, especially in winter and spring. It
309 is a cold, dry and strong wind unlike the easterly wind (from north-east to
310 south-east) that usually brings clouds, rain and waves.

314
315
316
317

318 *2.2. Model description*

319

320 The M.I.T General Circulation Model (MITgcm) is a primitive equation
321 ocean circulation model (Marshall et al., 1997). It is a z-coordinate finite-
322 volume model that solves the incompressible Navier-Stokes equations under
323 Boussinesq approximation, on an Arakawa-C grid. In this model, the free
324 surface equation is based on a pressure correction method. For this study,
325 we use the hydrostatic approximation. The time scheme is a quasi second
326
327
328
329
330

337
338
339
340
341
342
343
344 order Adams Bashford and the horizontal advection scheme is the third-order
345 DST (direct spacetime) flux limiter. The horizontal subgrid-scale mixing is
346 parametrised with the biharmonic Leith viscosity (see [Leith, 1968, 1996](#)).
347 Vertical background viscosity is set with $Az = 10^{-5} \text{ m}^2 \text{ s}^{-1}$, a standard value.
348 We use the turbulent closure scheme K-profile parameterisation (KPP) from
349 [Large et al. \(1994\)](#), to model vertical sub-grid scale mixing. For atmospheric
350 forcing, we use the bulk formulation from [Large and Yeager \(2004\)](#), and open
351 boundary conditions are prescribed and relaxed by a sponge layer. Free-slip
352 boundary conditions are applied at the bottom and on the lateral boundaries.
353
354
355
356
357
358

359 *2.3. MITgcm high-resolution configuration TBAY100*

360
361 The Toulon Bay domain spans a longitudinal range from 5.88° to 6.13°E
362 and a latitudinal range from 43.04° to 43.13°N (Fig. 1). The horizontal
363 mesh has 200x100 grid points with 100 m resolution. There are 75 depth
364 levels with a 50 cm minimum layer thickness at the surface, increasing to
365 about 30 meters near the seabed. Minimum depth is 3 meters and maximum
366 depth is 602 meters in the canyon at the south boundary (Fig. 1). The
367 timestep is 5 seconds. Outputs are saved every hour to catch most of the
368 dynamics variability. The TBAY100 configuration has two open boundaries
369 (south and west) and is forced with a NEMO-based configuration ([Declerck
370 et al., 2016](#)) which is a 1/192 degrees configuration of the Var coast (here-
371 after NIDOR192), including the Hyeres Bay and the “Îles d’Or” islands (i.e.
372 Porquerolles, Port-Cros and Levant; Fig. 1). Indeed, TBAY100 is the third
373 level of nested coarser models (GLAZUR64, NIDOR192). GLAZUR64 and
374 NIDOR192 have been validated during previous studies ([Ourmières et al.,
375 2011; Guihou et al., 2013](#)). The rigorous downscaling set-up guarantees good

400 confidence in the last and highest resolution configuration TBAY100. The
401 horizontal velocities and mass fields open boundary conditions are uploaded
402 daily. The operational global model ARPEGE from Meteo-France is used as
403 atmospheric forcing: it has a 1/10 degrees spatial resolution (about 9.5 km
404 at our latitude) and a 3 hours temporal resolution.
405
406

407
408 The starting date is the 1st of February 2016, after a 1 month simula-
409 tion (spin-up evaluated to 15 days). Initial conditions are computed from
410 NIDOR192 output.
411
412

413 414 *2.4. MITgcm ptracers package*

415
416 We used in this study the *ptracers* package from the MITgcm model.
417 This is a passive tracer package, in which the dissolved tracers do not affect
418 actively the physics of the ocean as they do not affect the water density.
419 Tracers are initialized with precise quantities (for details see Section 4), and
420 are released every time step.
421
422

423 424 *2.5. ADCP*

425
426 Horizontal velocity data from Acoustic Doppler Current Profilers (ADCP,
427 600 kHz, RDInstruments) were also used. Sampling frequency was 10 min.
428 Two ADCPs were moored in the south of the LB between January 2012
429 and April 2012 (see Fig. 1B). Their location were chosen to measure the
430 exchanges between the LB and offshore. ADCP 1 was located near Cape
431 Cepet and ADCP 2 was located near Cape Carqueiranne. The ADCPs were
432 bottom-moored at 32 m, and 29 m respectively. The water column was
433 divided into 35 1m-thick bins with the first bin at 2 m above the bottom.

456 *2.6. Diagnostics - composites pictures*

457
458 Previous studies on the area (Milot et al., 1981; Dufresne et al., 2014) con-
459 cluded that atmospheric forcings strongly influence hydrodynamics into the
460 Toulon Bay. Strong weather conditions cause highly variable currents (due
461 to various processes such as offshore swell, wind gusts,...) combined with
462 offshore waters intrusions and temporal reversals. The wind rose depicted in
463 (Fig. 2) is computed from the Meteo-France ARPEGE model dataset used
464 as external atmospheric forcings for the oceanic model (TBAY100). Two
465 major wind regimes can be defined accordingly:
466
467
468
469
470

- 471 1. A medium to strong Mistral (258.75 degrees to 326.25 degrees): a west
472 to north-west wind with an intensity between 6 and 24 m s⁻¹ (24.9 %
473 of the time);
474
475
- 476 2. A medium to strong easterly wind (56.25 degrees to 101.25 degrees): a
477 south-east to a north-east wind with an intensity between 6 and 24 m
478 s⁻¹ (9 % of the time);
479
480
481

482
483 When the wind intensity is lower than 6 m s⁻¹, we consider to be under
484 calm conditions (i.e. no wind). The circulation within the bay is therefore
485 analyzed for each wind condition. We averaged the horizontal velocity fields
486 associated with the specific wind regime, for the surface layer (0-5m) and
487 across the capes section (red line on Fig. 1) defining the LB limit. These
488 composites pictures are a powerful tool to highlight an average circulation
489 and its variability under specific conditions.

511
512 *2.7. Datasets*

513 Table 1 gives an overview of all data presented, and their date ranges. As
514 one of our main goal is to study contaminant dispersion, we have decided to
515 simulate the year 2016-2017 to coincide with dissolved copper observations
516 available for March 2017. Simulations are validated by a comparison with
517 ADCP observations obtained in 2012 (see section 2.5). In order to focus
518 on the wind-driven circulation, the velocities simulated by the model and
519 measured by the ADCP have been filtered. Data have been processed with
520 the PL66 filter (Limeburner et al., 1985), in order to filter all motions under
521 25h, including inertial oscillations, diurnal and semidiurnal tidal constituents
522 and eigen motions.
523
524
525
526
527
528
529

530 In the next sections, we will first identify the main circulation patterns
531 induced by regional wind characteristics and provide a quantitative valida-
532 tion using ADCP observations. Subsequently, results of 2 days simulations
533 with idealized wind conditions will be presented showing the principal con-
534 taminant dispersion pathways in the Toulon Bay. These simulations benefit
535 from the 1-month spin-up of the longer simulation TBAY100-PHYS. Even-
536 tually, the TBAY100-TRAC 14-month simulation will allow the assessment
537 of long-term temporal variability in contaminant dispersion, by running a
538 continuous contaminant release from 3 sources representing the main civil
539 ports in the SB (black dots on Fig. 1B).

Figure 2: Windrose for winds used as external forcings from Meteo-France ARPEGE model, from February 2016 to May 2017. Directions are divided into 16 slices of 22.5 degrees each. Mistral wind is composed of west-northwest winds with three main directions: d12, d13, d14 from 258.75 degrees to 326.25 degrees. Easterly wind is composed of east-northeast winds with three main directions: d3, d4 and d5 from 56.25 degrees to 123.75 degrees. Note the windrose shows the direction from where the wind blows.

736 **3. Circulation regimes**
737

738 *3.1. Surface composite pictures*
739

740 Composite pictures of surface currents (0-5m) for Mistral and easterly
741 wind, obtained with model results, show opposite current directions induced
742 by the two wind regimes (Fig. 3a,c). Overall, Mistral drags the surface
743 water southeastwards (Fig. 3a) enhancing the surface current intensity near
744 Cape Cepet and Cape Carqueiranne, whereas easterly wind pushes it towards
745 the north-west (Fig. 3c). While Mistral events drive the surface circulation
746 across the entire bay, the influence of easterly wind in the LB is limited
747 (indicated by the small arrows on Fig. 3c). However in the southern part of
748 the model domain, current intensities are higher and have a stronger gradient
749 compared to Mistral conditions. This may be due to intrusions of offshore
750 waters that amplify the local wind-driven current. To evaluate the relative
751 importance of these intrusions, we computed a transport index across two
752 transects (Fig. 3c and d), inspired from the method used by [Barrier et al.](#)
753 (2016) for the quantification of intrusions in the Gulf of Lion. While T1 (Fig.
754 4) allows us to trace the occurrence of surface offshore waters intrusions near
755 the southern boundary of the model domain, T2 identifies water intrusions
756 in the LB. The northward meridional current velocity was used to calculate
757 the positive transport T^+ across each transect over the surface (2 to 10 m
758 depth to focus on the core of the water intrusions). The transects locations
759 were chosen where the current intensities are large combined with a standard
760 deviation greater than 0.1 m s^{-1} for T1 and 0.05 m s^{-1} for T2 (Fig. 3c,d).
761 The T1 transect ends westward at the canyon location which is a natural
762 bathymetric guidance of offshore water intrusions. Transport is normalised

846
847 by its temporal mean $\langle T^+ \rangle$:
848

$$849 \quad I(t) = \frac{T(t)^+}{\langle T^+ \rangle} \quad (1)$$

850
851

852 We consider intrusions to occur when index $I(t) \geq 1$, i.e. when the
853 cross-section positive transport exceeds its mean. Fig. 4 represents the time
854 evolution between February 2016 and April 2017 of the wind (a), T1 (b)
855 and T2(c). As expected, most (94%) of the easterly wind episodes (grey
856 boxes) are associated with T1 intrusions. More than 13 periods reveal strong
857 intrusions with a high T1 index (up to 6-7).
858
859
860
861

862 Hence, during medium to strong easterly wind periods, offshore surface
863 waters are pushed toward the LB, bending in a cyclonic circulation at the bay
864 entrance. Whether or not the offshore waters enter the bay can be evaluated
865 by the T2 index. During three episodes (episodes 1, 2 and 6 in Fig. 4), a T2
866 index higher than 3 highlights the presence of an intrusion within the LB.
867 At other times (episodes 3,4 and 5), the T2 index remains below the index
868 value 3, indicating that the current mainly bypasses the LB. T2 intrusions
869 have been estimated to occur in the LB 78% of the time during easterly wind
870 episodes.
871
872
873
874
875
876

877 To evaluate the influence of the wind on the intrusion into the LB, a
878 scatter plot in Fig. 5 was used to represent the T1 and T2 indexes according
879 to the wind intensity and direction.
880
881

882 Very high values of T1 occur 16% of the time for E-NE strong winds (all
883 points circled by the black line in Fig. 5) corresponding to a non intrusion
884 circulation (T2 small), while high values of T2 (and T1 larger than 1) occur
885 with medium (around 8 m s^{-1}) north-easterly wind (90-120 degrees) (all
886 points circled by the red line in Fig. 5b). The wind direction combined with

its intensity seem to be the main forcings triggering intrusions of offshore water in the LB. The remaining 6% correspond to situations without intrusion near the southern boundary nor into the LB.

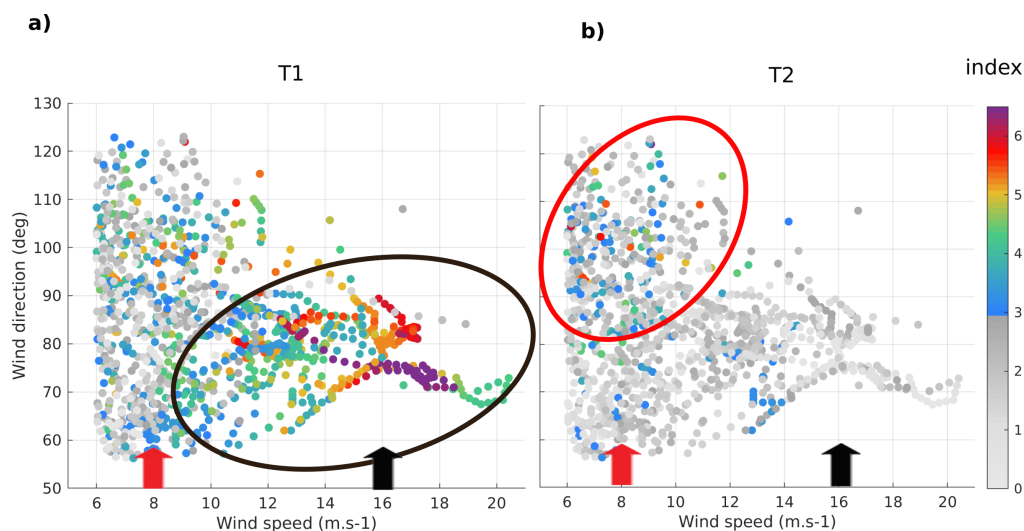

Figure 5: Scatter plot of wind speed (m s^{-1}) versus wind direction (deg). The colorbar indicates the value of T1 index (a) or T2 index (b). Red circle corresponds to winds with an entrance in the domain and in the LB. Black circle corresponds to winds with an entrance in the domain but no entrance in the LB. Red arrow corresponds to a wind of 8 m s^{-1} and black arrow corresponds to a wind of 16 m s^{-1} .

3.2. Cross-section composite pictures

After having investigated surface circulation, this section aims at studying the circulation through depth. To study the impact of wind conditions on the entire water column, circulation has been studied along a vertical cross-section between Cape Cepet and Cape Carqueiranne (red line in Fig. 1B).

For a medium to strong Mistral wind ($6\text{-}24 \text{ m s}^{-1}$), results show a bi-layer circulation into the bay (Fig. 6a), as it was shown for certain time periods by

Duffa et al. (2011). We clearly see here that the surface layer flows southward (blue) towards the open sea with a maximum mean value of 0.18 m s^{-1} near Cape Carqueiranne, whereas an incoming flow enters (red) the LB at the bottom of the water column (10-40 m). The average inversion depth is at ca. 10 m depth at the center of the channel, and it can deepens for strong winds.

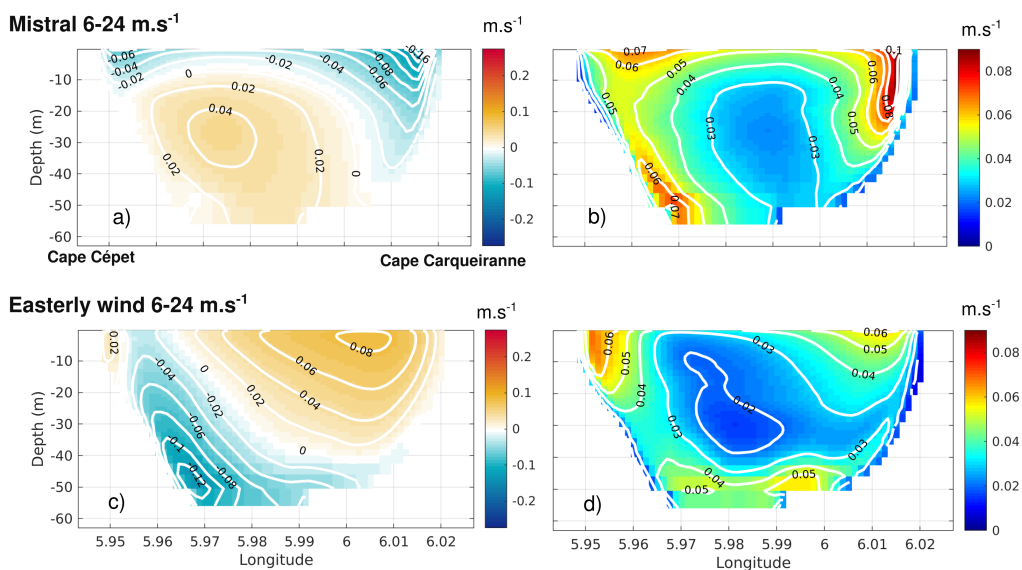

Figure 6: Left panels (a,c) are composite pictures of meridional velocity on a vertical cross-section between Cape Cépet and Cape Carqueiranne (red line in Fig. 1B). Right panels (b,d) are standard deviations of the meridional velocities for the composite pictures. Top panels (a,b) are for medium to strong intensity Mistral ($6 - 24 \text{ m s}^{-1}$), bottom panels (c, d) are for medium to strong easterly wind ($6 - 24 \text{ m s}^{-1}$).

In order to evaluate the occurrence of the bi-layer circulation, the meridional velocities were integrated at the surface (0-10 m) (blue box in Fig. 8a) and below the inversion depth (20-40 m) (red box in Fig. 8a) in order to avoid its variability. Results show that the bi-layer pattern, defined by a

inward surface flux, and outward deep flux, and according to our criteria, occurs for 81% of the Mistral events. The standard deviation on the outcoming current along Cape Carqueiranne (Fig. 6b) suggests that velocity variations are more important in this outflow compared to cape Cepet. A bathymetric effect is a probable explanation for this current acceleration near this cape induced by stronger wind. Overall the standard deviation of the meridional current across the vertical section has the same order of magnitude of the current itself. This can suggest that the bi-layer system may not be the only possible scheme.

Figure 7: Left panel (a) is a depth integration of meridional velocity on a cross-section between Cape Cepet and Cape Carqueiranne (red line in Fig. 1B) through number of Mistral events ($6 - 24 \text{ m s}^{-1}$). Right panel (b) is the standard deviation of the meridional velocity through time. Red and blue boxes are locations where $\text{STD} \geq 1.5$.

The transport across this section (Fig. 7b) for all the events corresponding to the Mistral regime is globally in the direction of the wind near the capes and upwind in the middle of the section. The same observation was first shown for an idealized long narrow lake by Csanady (1973), where the transport is downwind in shallow parts of the lake and upwind in deeper parts. This observation has also been made in the Gulf of Trieste a Mediter-

1185 drino et al., 2017) and in a shallow estuarine lake (Schoen et al., 2014) for
1186 wind-driven circulation.
1187

1188
1189 The Toulon Bay bi-layer pattern typical of the classic “wind driven chan-
1190 nel circulation” is the dominant pattern during Mistral wind conditions, oc-
1191 ccurring 81% of the Mistral-driven circulations. The composite picture result-
1192 ing in this BLP is depicted in Fig. 8a. The events are selected according to
1193 the transport value in the upper/lower layers imposed negative at the surface
1194 and positive at depth (blue/red boxes in the figure).
1195
1196
1197

1198
1199 Looking closer around the capes (boxes in Fig. 7b), the standard devia-
1200 tions of the integrated meridional velocity have very high values, exceeding
1201 $1.5 \text{ m}^2 \text{ s}^{-1}$, revealing inversions of the currents along the capes. In partic-
1202 ular, another possible circulation pattern can result from the Mistral wind
1203 regime, when the inflow (upwind) at the western Cape Cepet emerges and
1204 fills the whole water column. By extracting the remaining events, having an
1205 inflow at the western Cape, and an outflow at the eastern Cape (Fig. 8b,
1206 red boxes), an anticyclonic circulation within the LB is revealed during 13%
1207 of the Mistral events.
1208
1209
1210
1211
1212

1213
1214 Medium to strong easterly winds ($6\text{-}24 \text{ m s}^{-1}$) appear to generate an
1215 inward flow into the LB on the east side (Fig. 3c), with a core positioned at
1216 the surface near Cape Carqueiranne (Fig. 6c). The outflowing current follows
1217 the bathymetry at the westside of the cross section, near Cape Cepet, with
1218 its core at ca. 50 meters depth. A small confined inward current appears
1219 to occur at the edge of the cross-section (Cape Cepet), although standard
1220 deviations (Fig. 6d) show that its behaviour is very variable. Indeed, this

current can also disappear for instance when the surface current along the entire section enters the LB (not shown). Note that a significant fraction of the surface current bypasses the LB.

The analysis of the composite pictures described above, not only corroborates the previously identified highly variable nature of the hydrodynamics in the Toulon Bay (Duffa et al., 2011; Dufresne et al., 2014), but it also clearly allows to associate circulation patterns with typical wind characteristics.

3.3. Main circulation patterns

A qualitative and quantitative analysis of the model results, using the composite pictures described in section 3.1 and 3.2, allows the identification of four distinct circulation patterns, depending on the wind regimes and the offshore waters intrusions:

1. The Bi-layer pattern (*BLP*; Fig. 9a): the predominant circulation pattern during medium to strong Mistral events (81%). It occurs mainly with a west-northwest wind, with a median intensity of 8.88 m s^{-1} . It is characterised by a unidirectional surface outflow to the southeast towards the open sea inducing a bottom current entering the Toulon Bay (Fig. 8a). The maximum velocities observed near Cape Carqueiranne are due to a cape effect;
2. The Anticyclonic pattern (*ACP*, a derived circulation from the BLP pattern; Fig. 9b): a barotropic inward flow near Saint-Mandrier peninsula that follows the bathymetry in an anticyclonic way and leaves the LB near Cape Carqueiranne. This circulation pattern occurs 13% of medium to strong Mistral wind events. It occurs with a west to

1352 west-northwest wind, with a median intensity of 8.22 m s^{-1} and mostly
1353 during winter periods meaning the absence of stratification can play a
1354 role for its occurrence. In most cases, a small confined current flows
1355 southeastwards along the Saint-Mandrier peninsula (Fig. 8b);
1356

- 1358
1359 3. The Intrusion pattern (*IP*; Fig. 9c) : an inward flow near Cape Car-
1360 queiranne, caused by an offshore waters intrusion into the LB during
1361 easterly wind events (with median intensities of 9.15 m s^{-1}). This pat-
1362 tern has been highlighted by a transport analysis to detect offshore
1363 waters intrusions into the LB. It has been identified to occur for 78%
1364 of the time when easterly winds exceed 6 m s^{-1} and for wind from 80
1365 to 120 degrees most of the time. South of the open boundary line, this
1366 circulation pattern has a cyclonic character, probably mainly driven by
1367 the along-coast pathway of the NC. These offshore waters intrusions
1368 depend on the upstream circulation features, and more specifically on
1369 whether an NC intrusion into the Hyeres Bay has occurred (Declerck
1370 et al., 2016).
1371
1372
1373
1374
1375
1376
1377
1378 4. The Non Intrusion pattern (*NIP*; Fig. 9d) : this derivated regime from
1379 the IP pattern has also an anti-clockwise circulation south of the open
1380 boundary line, induced by medium to strong easterly wind events with
1381 a predominant northeast direction (60 to 90 degrees) to with a median
1382 intensity of 15.18 m s^{-1} , which is greater than for the IP pattern. It
1383 occurs 16% of the time when easterly winds exceed 6 m s^{-1} . This
1384 pattern is characterized by strong current intensities located mainly
1385 south of the LB and by no waters intrusions in the LB.

circulation patterns can be differently chosen, and may give slightly different percentage of occurrence. However, the four patterns are clearly present in the simulations, and this will be confirmed with the distribution of contaminant (section 4).

3.4. Validation with in-situ observations

The Toulon Bay model TBAY100 is the third level of nested coarser models (GLAZUR, NIDOR) (see section 2.3), with accurate forcings at the southern and western boundaries. Nevertheless, validations with in-situ observations is necessary and will emphasis our confidence in the previous results. In-situ current observations in such coastal areas are scarce. ADCP data were only available from January to April 2012. The model results are compared to these ADCP observations by sorting and averaging the velocities obtained during the two typical wind conditions of the area. Surface (top 2.5 m) and bottom currents (28 m) resulting composites, computed by the model and recorded by both ADCPs at Cape Carqueiranne and Cepet, are presented in the current rose diagrams in Fig. 10 as average percentages through the ADCP deployment period and the total period of the model simulation. The figure is split in 4 boxes: left ones correspond to Cape Cepet ADCP analysis, right ones correspond to Cape Carqueiranne; upper blue boxes correspond to Mistral wind regime, and lower orange ones to easterly wind regime. In each box 4 current roses are designed for the observation, the model, the surface and the bottom.

At Cape Cepet, during medium and strong Mistral winds, (upper left box) surface modelled and observed currents flow towards the same direction, i.e. south-east (Fig. 10a and b), although modelled intensities are stronger

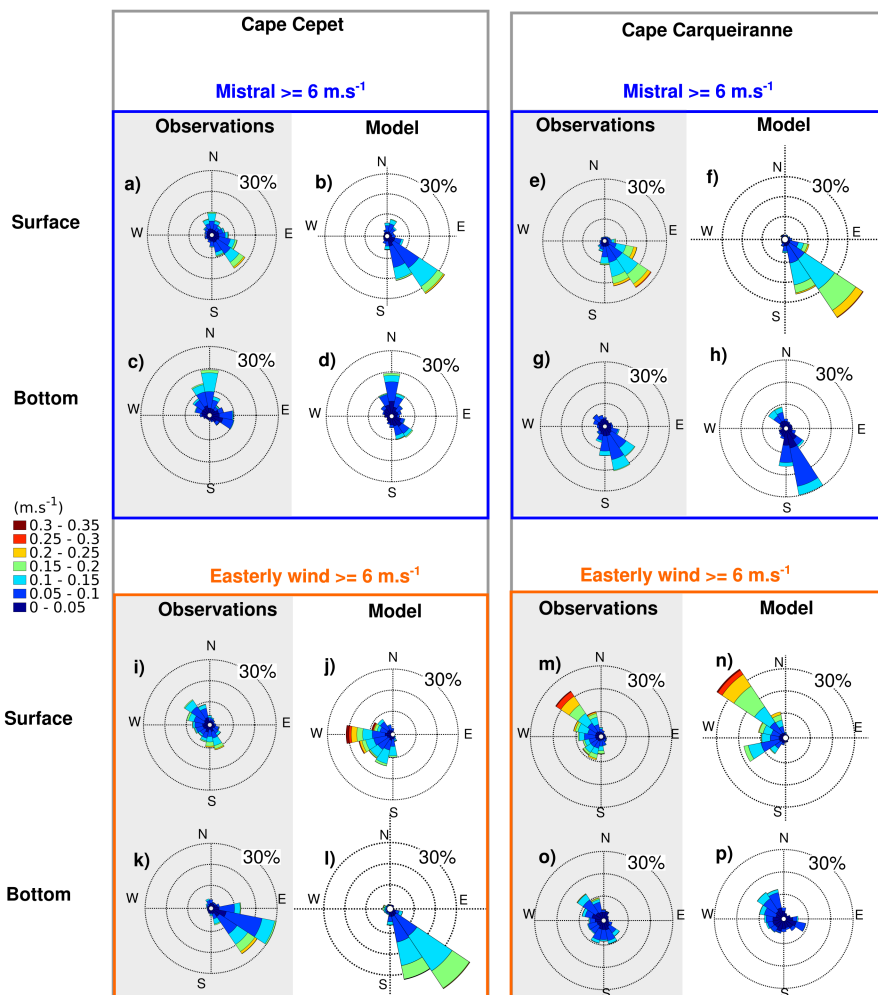

Figure 10: Current roses (m s⁻¹) for ADTCP observations and model output at location Cepet (left-hand side), and Carqueiranne (right-hand-side). Blue boxes (top) are for medium to strong Mistral conditions, orange boxes (bottom) for medium to strong easterly wind condition. For each box, observations (left) and model output (right) are represented for surface (top) and bottom (bottom) currents. Note current roses show the direction towards which the current flows.

1519
1520 (0.35 m s⁻¹ versus 0.20 m s⁻¹). At the bottom, current intensities and
1521 directions are overall the same, though observations show more variability
1522 in direction (Fig. 10c and d). For medium and strong easterly wind events
1523 (lower left box), differences appear between modelled and observed surface
1524 currents (Fig. 10i and j). While the observations show a north-westwards
1525 and south-southeastward flow with a maximum intensity of ca. 0.20 m s⁻¹,
1526 modelled currents flow towards the west to south-west at a significant higher
1527 velocity. At the bottom, currents have similar directions, flowing towards the
1528 south-east, with slightly more intense modelled currents (Fig. 10k and l). A
1529 possible explanation for the mismatches between the ADCP and model data
1530 (mostly situations in Fig. 10i and j), is the bathymetry approximation in
1531 the TBAY100 model, in particular near the capes, where the bathymetry is
1532 shallow and steep. We observe in the model outputs that current variability
1533 is very important near the Cape Cepet location and that this location is near
1534 the area where the current bypasses the LB in the model.

1541
1542
1543
1544
1545 At Cap Carqueiranne, during medium and strong Mistral winds (upper
1546 right box), surface currents are stronger than at Cape Cepet and can reach
1547 up to 0.25 m s⁻¹ during this period (Fig. 10e and f). Surface modelled and
1548 observed currents have similar directions and are flowing to the south-east
1549 out of the large bay. At the bottom, modelled and observed currents are
1550 weaker than at the surface (a maximum of ca. 0.15 m s⁻¹) but they have
1551 almost the same directions, i.e. south-southeast for both model and obser-
1552 vations (Fig. 10g and h). Accordingly, model and observations are very
1553 coherent at Cape Carqueiranne for Mistral conditions both in intensity and
1554 direction. During medium and strong easterly wind (lower right box), sur-

face currents flow north-westwards with a maximum intensity of 0.3 m s^{-1} for both model outputs and observations (Fig. 10m and n), which may correspond to an intrusion of offshore waters into the LB. Overall, the observed surface currents at the Cape Carqueiranne location seems to be more responsive to wind, as they appear to be stronger than at Cape Cepet, and are approximately downwind for both wind conditions. Finally, bottom currents during medium and strong easterly wind are weaker compared to the surface currents and have the same maximum intensity of 0.15 m s^{-1} for modelled data and observations. While the observed currents do not have a dominant direction, the modelled currents flow north-westwards and south-eastwards (Fig. 10o and p).

To summarize, the model results are coherent with most of the observed velocities direction at the ADCP locations. In terms of intensity, the model overestimates most of the time the occurrence and the intensity. The most important discrepancies appear at the western side of the LB boundary, at Cape Cepet, during easterly wind regimes, in particular at the surface. However the current rose of the ADCP (Fig. 10i) and of the model, do not show clear dominant currents, indicating that the circulation is very variable in this particular location. This variability is confirmed by the model results suggesting (Fig3a & 8b) that for the anticyclonic circulation, offshore waters may enter or not into the LB, leading to a different response at the ADCP location. Moreover we should recall that the ADCP experiment lasted 4 months in 2012 and the model simulation from February 2016 to April 2017. Interannual and seasonal variability could also explain part of the discrepancies.

If we compare the schematic circulations suggested by the model outputs and presented in the previous sections, during mistral regime the results are very coherent with both the BLP and the ACP. During easterly wind regime, the NIP appear at the bottom but not clearly at the surface. More ADCP moorings would be necessary to validate this circulation suggested by the simulations.

In conclusion, several factors influence the hydrodynamics of the Toulon Bay: the preceding conditions, offshore waters intrusions, wind intensity and direction. The important impact of wind on hydrodynamics within small semi-enclosed bays, was also observed in the Gulf of Fos, where wind events have a stronger influence on hydrodynamics than the shelf offshore current (Ulses et al., 2005). Even in small basins under strong tidal influence, wind events may interfere on local circulation, such as in Southern Australia (Black et al., 1993). The circulation patterns identified in this section highlight the possible export paths for contaminants which are discussed in the next section.

4. Contaminant distribution

Now that the circulation has been validated, the second objective is to better understand the distribution of contaminant in the area.

Chemical analysis of surface seawater samples from the Toulon Bay, obtained within the projects METFLUX, PREVENT and the MERMEX program by N. Layglon (MIO, University of Toulon) following an established method (Jean et al., 2012), have revealed the presence of elevated copper concentrations in March 2017, varying from 3 nM in the LB to 113 nM in

the SB (Fig. 11). While the distribution of dissolved copper is relatively uniform in LB (and close to background concentrations for the Mediterranean Sea, 1.6 nM; (Tovar-Sanchez et al., 2014)), steep concentration gradients were observed in the SB with maximum values measured in the docks of the civil (113 nM) and navy (67 nM) ports of Toulon and in the civil ports of La Seyne-sur-Mer (40 nM) and Saint-Mandrier (82 nM). This is in agreement with previous observations (e.g. Coclet et al., 2018), hence these ports can be considered as point sources of dissolved copper to the bay. Common sources of copper in harbours are antifouling paints which are applied to the hulls of boats to prevent growth of fouling organisms (e.g. Schiff et al., 2007). Since the ban of triorganotin formulations, most modern marine antifouling paints contain a Cu-based biocidal pigment (Turner, 2010) which has led to increased levels of dissolved copper in coastal waters, especially in and near ports (e.g. Biggs and D’Anna, 2012; Warnken et al., 2004). Accordingly, antifouling paints are hypothesised to be a major source of dissolved copper to the Toulon Bay.

To understand and evaluate the impact of the elevated levels of dissolved copper on the water quality of the Toulon Bay, distribution patterns were modelled under the influence of different wind conditions and seasonal variability was assessed via a 14-month simulation. Copper has been shown to have a high affinity for organic matter in the marine environment, forming dissolved organic copper species (e.g. Buck et al., 2007). Its distribution can thus be modelled as a passive tracer. Based on the surface distribution map of dissolved copper (Fig.11), copper was released as a passive tracer at three sources in the TBAY100 model: the civil ports of (1) Toulon, (2) la Seyne-

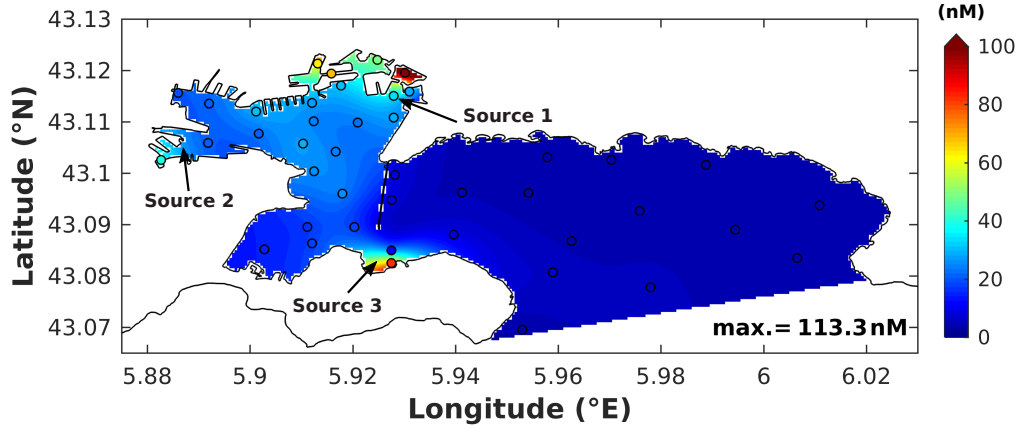

Figure 11: Sea surface distribution of copper (nM) measured on 20 March 2017 (av. wind speed and direction: 2.4 m^{-1} SE). Positions of the three contaminant sources in the TBAY100 model: Toulon civil port (source 1), la Seyne-sur-Mer civil port (source 2), and Saint-Mandrier civil port (source 3).

sur-Mer and (3) Saint-Mandrier (see Fig. 1B for the precise location in the TBAY100 model). As the majority of the berths in the ports are occupied year-round, copper leaching from anti-fouling paints is considered to be a constant process and was therefore modelled as a continuous source. The quantity of copper released per time step at each source (Cu_{source} ; nmol dt^{-1}) was calculated based on the capacity of each port (i.e. number of berths) using the following equation:

$$Cu_{\text{source}} = N_{\text{berths}} \times S_{\text{mean}} \times AR \times dt \quad (2)$$

where N_{berths} is the number of berths per port, S is the standard estimate for wetted hull surface area (i.e. 41 m^2) of a typical recreational boat (12 m long with a beam of 4 m) used by paint manufacturers (i.e. the length

by the beam width by 0.85, a standard conversion factor; Earley et al. (2014)) and AR is an average release rate of antifouling paint ($6.9 \text{ nmol m}^{-2} \text{ s}^{-1}$). The latter is based on estimates for cumulative passive copper leaching (i.e. without considering cleaning activities and boat usage) during a typical paint life cycle of three years for 2 types of paint (4164 ug cm^{-2} or $1388 \text{ ug cm}^{-2} \text{ yr}^{-1}$ which corresponds to $6.9 \text{ nmol m}^{-2} \text{ s}^{-1}$), which was derived from in situ measurements in San Diego Bay (Earley et al., 2014). Accordingly, AR provides a minimum baseline for leaching rates of Cu from antifouling paints into the marine environment.

Table 2: Estimates of copper release rates at the three identified point sources in Toulon Bay. N_{berths} is the number of berths per port, and Cu is the quantity of copper released per time step (nmol/5s)

	N_{berths}	Cu (nmol/5s)
Source 1 (Toulon civil port)	982	1.5×10^6
Source 2 (la Seyne-sur-Mer)	300	4.5×10^5
Source 3 (Saint-Mandrier)	800	1×10^6

4.0.1. Wind dependent contaminant distribution patterns

As shown in section 3.3 several circulation patterns could be correlated with two main wind directions: the Mistral and the easterly wind. The circulation patterns were depending on the wind intensity and direction for the former and the existence of offshore waters intrusions for the latter. The influence of these four circulation patterns on the dispersion of dissolved contaminants in the Toulon Bay was examined by running idealized simulations,

imposing a constant wind during 2 days instead of using the ARPEGE atmospheric model as external wind forcings. Care was taken to select two days with wind conditions similar to the imposed one, to avoid too important numerical instabilities, and a possible model blow-up. The same patterns were obtained for multiple dates for each of the four wind case scenarios and associated circulation patterns: 1) Mistral 8 m s^{-1} (ACP), 2) Mistral 16 m s^{-1} (BLP), 3) easterly wind with offshore waters intrusion (IP) and 4) easterly wind without offshore waters intrusion (NIP), underlining the representativeness of these contaminant distribution patterns for each scenario.

At medium wind intensity (8 m s^{-1}), the plume of dissolved contaminants released in the SB spreads into almost the entire LB (Fig. 12-A1). Overall concentration maxima occur at the surface in the entire bay with exception of a small eddy, which is formed at the exit of the SB. This contaminant plume is originated from source 2 and 3 that are evacuated from the SB during the time span of 2 days. The waters exiting the SB encounter an incoming vein flowing westward into the LB and mix because of this front preventing them from spreading in the whole LB. The SB waters bypass this front by following an anticyclonic motion into the LB, spreading the contaminant at the surface of the LB (Fig. 12-A2). The dispersion of the contaminants released at the Toulon civil port (source 1) remains confined to the northeast sector of the SB. Mistral winds of high intensity (16 m s^{-1}) export dissolved contaminants to the LB and beyond, until the Giens peninsula, in 2 days time (Fig. 12-B1) demonstrating the wind-driven circulation in the Toulon Bay area. The majority of the contaminants remain at the surface (Fig. 12-B2).

In the case of easterly winds, simulations have demonstrated that the

presence or absence of offshore waters intrusions is the determining factor defining the contaminant distribution patterns. It is correlated with wind characteristics (intensity and direction), so that a medium SE wind induces an entrance of offshore waters into the LB whereas a strong NE wind tends to prevent an intrusion of waters into the LB. During easterly wind conditions with an intrusion into the LB (corresponding to the intrusion pattern and a wind of medium intensity), the contaminant plume is exiting the Toulon Bay at depth along a narrow route around the Saint-Mandrier peninsula (Fig. 12-C1), following the bathymetry. Passed this cape, pollutants resurface on the south coast of the peninsula while remaining at mid-water depths further offshore. Once at this point, pollutants are likely taken up in the NC and quickly exported westwards along the coast. Without offshore waters intrusions in the LB, with a strong easterly wind, contaminants are distributed over the entire LB and are evacuated following the passageway along the Saint-Mandrier peninsula (Fig. 12-D1). While the dissolved contaminants remain on the surface, in the SB they sink to the bottom once passed the seawall. Passing the peninsula, the contaminant plume mainly follows the bathymetry.

In conclusion, the model shows that, outside of the Toulon Bay, especially the south coast of the Saint-Mandrier peninsula is directly subjected to frequent plumes of dissolved contaminants (for 2 out of 4 scenarii, which corresponds to medium and strong easterly wind periods or 9% of the total time). As the contaminants show a tendency of staying in surface layers, extra vigilance may be required for the quality of surface waters in this area. Furthermore, dissolved contaminants, originating from Toulon Bay,

may reach the Marine National Park of Port-Cros, under mainly strong Mistral winds driving a bi-layer circulation pattern which is estimated to occur ca. 20% of the time, given that medium to strong Mistral correspond to 24.9% of the total time. Accordingly, the impact of Toulon Bay's contaminated waters on the National Park appears possible, which warrants further investigation using a model with a domain that extends to the National Park.

4.0.2. Seasonal variability of contaminant dispersion

A 14-month simulation was conducted to assess the seasonal variability of dissolved contaminant distributions in the Toulon Bay. Therefore the Cu distribution map in Fig. 11 (based on 42 observations) was used as initial condition and copper was released at a continuous rate (Table 2) from the three point sources. The main interest of this simulation is to evaluate the potential impact of contaminant release on surface waters (top 5 m of the water column) in recreational zones such as near beaches and in areas exploited for aquaculture, where water quality may impact public health. Accordingly, Fig. 13 shows the temporal variation in dissolved copper at the highly frequented beaches of Mourillon (Large Bay), the aquaculture site Lazaret (Small Bay) and, for comparison, the northern SB close to sources 1 and 2 (Fig.1B). The model results show that at the three locations, the surface waters are more concentrated in dissolved copper (up to 5 times the background signal) during spring and early summer. This may be due to the fact that this period is generally characterized by winds with a lower intensity (Fig. 13), which implies weaker surface currents and longer residence time (Dufresne et al., 2014). As dissolved contaminant dispersion is wind-driven in the SB, the dispersion of dissolved copper is reduced and an accumulation can

be observed in the entire SB. On the other hand, medium Mistral wind (6-10 m s⁻¹) with an anticyclonic pattern (Fig. 9b), is probably responsible for the observed elevated copper concentrations in the waters of Mourillon (Fig. 12-A2). Accordingly, the observed pattern of a degraded water quality in spring-summer in the Toulon Bay, merits to be tested in the future with observations to validate the coupled hydrodynamic and passive tracer model as a useful tool for pollution management. The low dissolved copper concentrations in winter, are mostly likely due to the stronger wind intensities (> 15 m s⁻¹) and the frequent alternation between Mistral and easterly winds promoting water exchanges between SB and LB as demonstrated by [Dufresne et al. \(2014\)](#).

The 1-year simulation is not sufficient for the contaminant continuously released at the source points to impact the far east side of the bay. Therefore, the temporal variability of contaminant dispersion will not be discussed for the beaches located at the far east side of the TBAY model domain.

Nonetheless, copper concentrations in these areas remain close to background values for the Mediterranean Sea (i.e. 1.6 nM; [Tovar-Sanchez et al. \(2014\)](#)) after one year. Although seasonal variability was the focus of the 14-month simulation, a validation of the tracer model was performed, comparing the Cu concentration map with the model output for the same day, 20 March 2017. This comparison shows that the surface Cu concentrations are underestimated compared to the measured values (Fig. S1 and S2 in Supplementary Material), while the concentration gradient across the Toulon Bay is reproduced. The estimates are especially low in the small bay which is most likely due to the minimum Cu leaching rates used in the model (section

2192 4). The latter do not take into account boat cleaning activities and boat
2193 traffic, two activities that are particularly concentrated in the small bay (but
2194 difficult to quantify) and are known to have an impact on Cu leaching from
2195 antifouling paints. Accordingly more efforts are needed in quantifying Cu
2196 leaching rates to improve copper distribution modelling studies in coastal
2197 areas, where antifouling paints are likely a major source of Cu.

2203 **5. Conclusions with discussion**

2204

2205 The aim of this study was to investigate circulation patterns and scenarii
2206 of contaminant dispersion depending on weather conditions, thanks to the
2207 very high resolution configuration TBAY100 (configuration set up with the
2208 MITgcm ocean model). As previous studies focused on the exchange between
2209 SB and LB, this study focused on the circulation occurring in the LB and
2210 the exchanges with offshore waters, to assess the potential impact of the
2211 heavily contaminated waters of Toulon Bay on the surrounding environment,
2212 including the Marine Port-Cros National Park.
2213
2214
2215
2216
2217
2218

2219 Model simulations have highlighted that the circulation in Toulon Bay is
2220 mainly wind-driven. However, offshore waters intrusions do occur and can
2221 induce strong currents inside the bay. These intrusions may be NC intrusions
2222 as in the Hyeres Bay upstream and an assessment of this hypothesis would be
2223 part of a future work. The tides contribute only for 3-4 cm on average of the
2224 free surface elevation, with a maximum of 20 cm in our zone, as confirmed by
2225 local observations (Rey et al., 2019). Therefore, we can say that the tide has
2226 a minor impact compared to other forcings. Overall, four circulation patterns
2227 could be identified. Medium to strong Mistral events do most frequently (81
2228
2229
2230

2244
2245
2246
2247
2248 %) generate a Bi-layer pattern and less often (13 %) an Anticyclonic pattern.
2249 In both patterns, the plume of dissolved contaminants spreads at the sur-
2250 face over the entire LB, but in summer period, the contaminant plume flows
2251 towards the Giens peninsula. The anticyclonic circulation appears mostly
2252 during winter periods suggesting that the absence of stratification can play
2253 a role for its occurrence. The impact of stratification on this schematic cir-
2254 culation will be addressed in a future work. When the wind episode is long
2255 enough and considering the frequent occurrence of the Bi-layer pattern, there
2256 could be exchanges of contaminants with the Hyeres Bay and the Port-Cros
2257 National Park. Medium to strong easterly winds induce offshore waters in-
2258 trusions into the LB (78 %) associated with a cyclonic circulation (Intrusion
2259 Pattern). Under these conditions, contaminants are spreading into a nar-
2260 row vein above the bottom, flowing around Saint-Mandrier peninsula before
2261 probably meeting the NC offshore. At the same time, it can also spread
2262 inside the LB before being carried offshore Saint-Mandrier peninsula if there
2263 is no offshore waters intrusion into the LB (Non Intrusion Pattern).

2304 out, focusing on vertical movements, at very short time and space scale.

2305 As to optimise predictions of contaminant distribution in this exception-
2306 ally polluted area, an increment and adjustment of locations of moored
2307 ADCP locations is envisaged in the near future, as well as an assessment
2308 of non hydrostatic effects on the circulation in Toulon Bay. Moreover, other
2309 suggestions for future work are: evaluating the dispersion of contaminants
2310 toward the Marine National Park Port-Cros using a model domain incor-
2311 porating the park and implementing a sedimentary package into the model
2312 as to model also dispersion patterns for contaminants with a high particle
2313 affinity such as lead.

Supplementary Material

Validation of tracer simulation

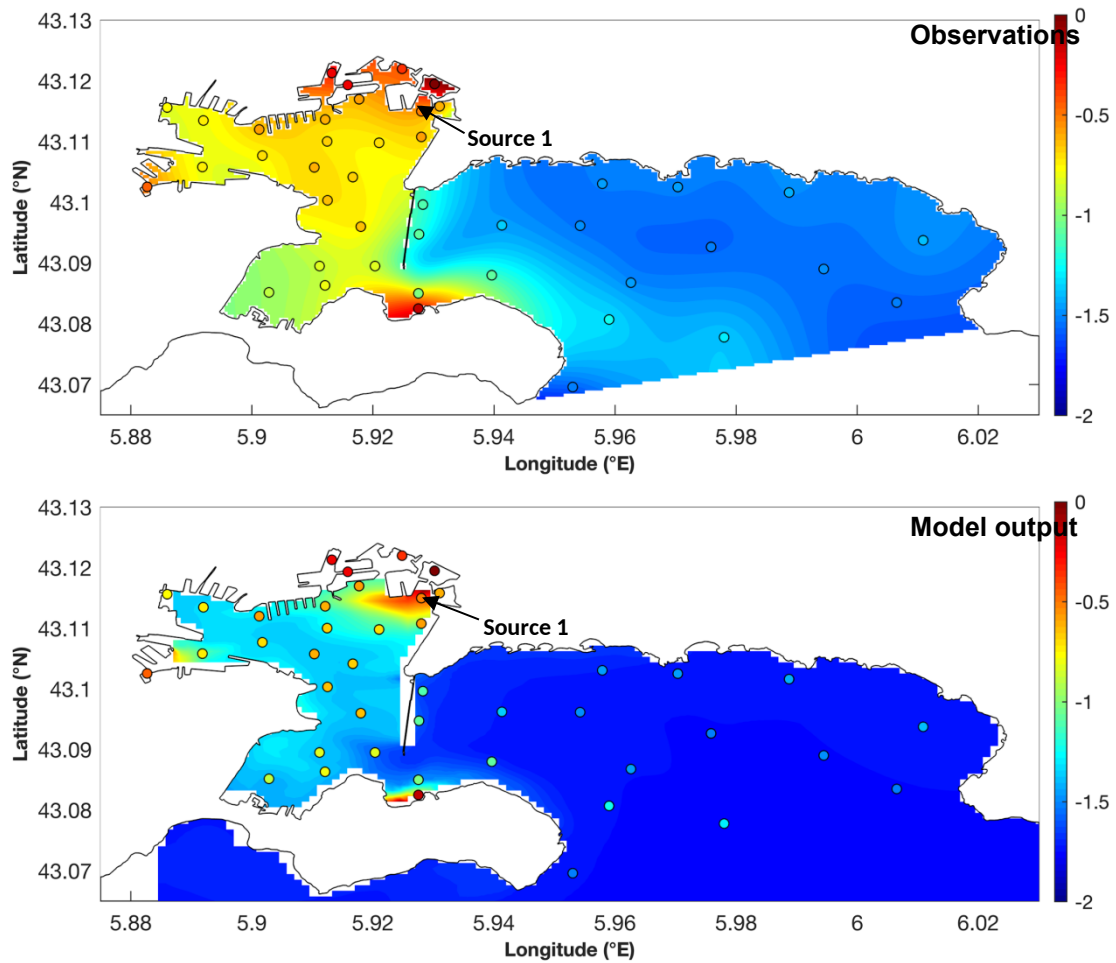

Figure S1: Validation of tracer simulation. **A**) Surface distribution of dissolved Cu concentrations measured on March 20th 2017 at 1 m depth, normalized to the maximum concentration value measured i.e. at source 1, Toulon Port (log₁₀ scale). **B**) Modelled surface distribution of dissolved Cu at 1 m depth on March 20th 2017 averaged over the duration of sample collection (12h, from 6:00 till 18:00), normalized to the maximum concentration value simulated i.e. at source 1, Toulon Port (log₁₀ scale). Colour filled dots in both figures are the Cu concentrations measured at observation points (at 0.5 m depth) normalized to the maximum concentration measured i.e. at source 1, Toulon Port.

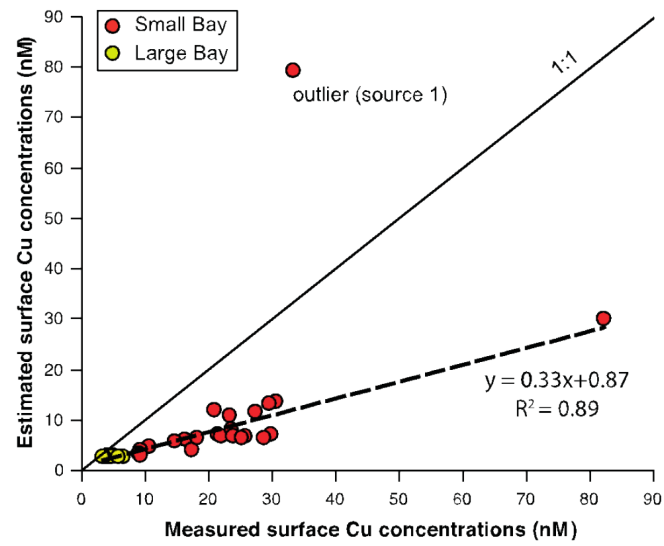

Figure S2: Correlation between the measured and estimated Cu surface concentrations at the observation sites shown in figure 1. The outlier was excluded from the regression analysis.
